## Abstract

In a two-country DSGE model, the effects of foreign demand shocks on the home country are greatly amplified if the home economy is constrained by the zero lower bound on policy interest rates. This result applies even to countries that are relatively closed to trade such as the United States. Departing from many of the existing closed-economy models, the duration of the liquidity trap is determined endogenously. Adverse foreign shocks can extend the duration of the trap, implying more contractionary effects for the home country. The home economy is more vulnerable to adverse foreign shocks if the neutral rate is low – consistent with “secular stagnation” – and trade openness is high.

**Keywords:** zero lower bound, spillover effects, DSGE models.

# 1 Introduction

For large and relatively closed economies such as the United States, foreign shocks have typically been perceived as having small effects on domestic output. This view accords with the Mundell-Fleming model, which implies that monetary policy can offset the effects of foreign shocks on domestic production. This view is also consistent with analysis based on open economy DSGE models.<sup>1</sup> Moreover, it would seem to be confirmed by actual experience during the Great Moderation, a period in which the U.S. economy typically performed well despite several major recessions in key U.S. trading partners, including during the Mexican crisis in the mid-1990s, the Asian and Russian default crises in the late 1990s, and over long periods in which Japan's growth sputtered.

However, developments during the Global Financial Crisis (GFC) and its aftermath suggest that foreign shocks may have much larger effects on the domestic economy when monetary policy is constrained from adjusting interest rates due to the zero lower bound (ZLB). Indeed, Japan's experience during the GFC seems a telling illustration. As seen in Figure 1, financial developments in Japan during the GFC were much less adverse than in the United States or euro area – with corporate bond spreads rising much less (the top panel). However, the Bank of Japan had little scope to cut policy rates (the middle panel) in response to the massive collapse in global demand that occurred in 2008-2009 and Japan experienced a comparatively larger GDP contraction (the bottom panel). In a similar vein, U.S. policymakers during the past several years have often pointed to foreign developments as playing a key role in affecting the U.S. outlook, and have argued that potential spillovers

---

<sup>1</sup>Drawing on the two country real business cycle model of Backus, Kehoe, and Kydland (1992), Baxter and Crucini (1995) show that a positive country-specific productivity shock in the foreign economy induces a small *contraction* in domestic output. Similarly, Lubik and Schorfheide (2006) and Adolfson, Laseen, Linde, and Villani (2007) show cross-border spillovers are very small even in models including nominal rigidities.

from abroad are likely to be larger due to the ZLB.<sup>2</sup>

In this paper, we conduct a more formal analysis of how the ZLB constraint on policy rates affects the transmission of foreign shocks to the United States using an open economy DSGE model. Our model incorporates a wide array of empirically-relevant features that we calibrate to the U.S. economy, including sticky wages and prices, endogenous capital accumulation (with adjustment costs), and local currency pricing for traded goods.<sup>3</sup> We show that the effects of a given-sized foreign demand shock are much larger than in normal times if the foreign shock occurs against the backdrop of a severe domestic recession that pins domestic policy rates at zero. In particular, under our baseline calibration, a shock that reduces foreign GDP by 1% causes U.S. GDP to fall by roughly 0.6% in a ten quarter liquidity trap, a drop about twice as large as would occur if U.S. policy rates could be freely adjusted according to a Taylor rule. The larger effects reflect that in normal times policy rates can be cut to crowd in domestic demand, but that such crowding in is attenuated in a liquidity trap.

We next investigate how the effects of foreign shocks depend on the assumed long-run level of the neutral policy rate, i.e., the policy rate consistent with full-employment after economic shocks have worn off. Ball, DeLong, and Summers (2014) argued that the neutral interest rate may in fact be very low for many industrial economies compared with post-war norms, a phenomenon termed “secular stagnation.” As suggested by Japan’s experience, a drift toward secular stagnation could heighten the vulnerability of many of these economies to a downturn in foreign demand. In this vein, we show how a foreign demand shock could *by itself* push an economy with a low neutral nominal rate into recession, i.e., even assuming that the domestic economy was near full employment prior to the shock. Moreover, we illustrate that the effects of the foreign downturn on the domestic economy can be sharply nonlinear if the shock is large enough to push the economy into a liquidity

---

<sup>2</sup>For a recent example, see Brainard (2015).

<sup>3</sup>See Christiano, Eichenbaum, and Evans (2005) and Smets and Wouters (2003).

trap, and/or extend its duration. This is important, because it emphasizes how recessions can be caused purely by foreign shocks operating through trade channels, even in the absence of financial spillovers (from which our model abstracts).

Although the rise in global trade during the past few decades has likely had many beneficial effects – allowing, for instance, countries to specialize production based on their comparative advantage – our analysis shows how greater trade openness may heighten vulnerability to adverse foreign developments when the ZLB is binding. Intuitively, while foreign demand shocks should amplify the contribution of net exports to GDP as the trade share rises, monetary policy should be able to offset these larger trade effects on GDP through appropriate adjustment of policy rates if the ZLB does not bind; thus, foreign demand shocks should not be expected to cause substantially greater output volatility simply on account of a higher trade share.<sup>4</sup> However, our model simulations illustrate how a higher trade share can translate into much larger effects of foreign shocks on domestic output if the ZLB binds, and in particular, underscore the potential challenges posed by the interaction of greater trade openness and secular stagnation.

From a broader perspective, our analysis of the effects of foreign shocks has a close parallel with the (largely) closed economy literature emphasizing that domestic shocks have outsized effects in a liquidity trap, reflecting that adverse shocks cause the real interest rate to rise (while favorable shocks, including fiscal stimulus, cause the real rate to fall), e.g., Christiano, Eichenbaum, and Rebelo (2011a), Eggertsson (2011), and Woodford (2011). Even so, most of the literature has highlighted the role of either domestic factors or cross-border financial spillovers as the likely catalyst for pushing an economy to the ZLB. Accordingly, the literature has emphasized the desirability of developing a policy framework that minimizes the risks of a financial meltdown arising from either domestic or foreign sources. Our analysis indicates

---

<sup>4</sup>Consistent with this implication, Doyle and Faust (2005) found that the correlation between U.S. growth and that of its major trading partners showed little tendency to rise as trade ties deepened.

that the spillovers from foreign shocks – operating purely through trade channels, and absent any financial contagion – could be very large for economies that are highly open with a low nominal rate. Given these large trade spillovers, keeping “one’s own house in order” may not be enough to minimize ZLB risks.<sup>5</sup>

A methodological contribution of our paper is to adopt a modeling framework in which the duration of the ZLB depends endogenously on the foreign demand shock, which allows the effect on GDP to rise nonlinearly with the size of the foreign shock.<sup>6</sup> We also show that the amplified effects of the ZLB is quite particular to demand shocks, and reflects that an adverse foreign demand shock hurts home real net exports both through reducing foreign activity, and by appreciating the domestic currency.<sup>7</sup> By contrast, the ZLB has negligible consequences for the effects of foreign technology shocks, reflecting that adverse foreign supply shocks tend to depreciate the domestic currency, which mitigates the adverse effects on exports.

## 2 The Model

Apart from the explicit treatment of the zero-lower bound on policy rates, our two-country model is close to Erceg, Guerrieri, and Gust (2006) and Erceg, Guerrieri, and Gust (2008) who themselves build on Christiano, Eichenbaum, and Evans (2005) and Smets and Wouters (2003). We focus on describing the home country as the

---

<sup>5</sup>Related work by Eggertsson, Mehrotra, and Summers (2016) shows how secular stagnation can be transmitted across borders through financial market integration. Focusing on the steady state of a two-country overlapping generations model, they show how chronic weakness in one country can drag the global economy into a permanent liquidity trap.

<sup>6</sup>This approach contrasts with much of the literature, which typically assumes that the shocks considered are too small to affect the duration of the liquidity trap, including in the two-state Markov switching framework often used in heuristic models, e.g., Eggertsson (2011), and Woodford (2011).

<sup>7</sup>Stockman and Tesar (1995) extended the model of Backus, Kehoe, and Kydland (1992) to include consumption preference shocks, and highlighted how these shocks have different implications for cross-country co-movements than technology shocks even in their framework which abstracted from nominal frictions.

setup for the foreign country is analogous. The calibration for the home country reflects key features of the United States.

## 2.1 Firms and Price Setting

*Production of Domestic Intermediate Goods.* There is a continuum of differentiated intermediate goods (indexed by  $i \in [0, 1]$ ) in the home country, each of which is produced by a single monopolistically competitive firm. Firms charge different prices at home and abroad, i.e., they practice pricing to market. In the home market, firm  $i$  faces a demand function that varies inversely with its output price  $P_{Dt}(i)$  and directly with aggregate demand at home  $Y_{Dt}$  :

$$Y_{Dt}(i) = \left[ \frac{P_{Dt}(i)}{P_{Dt}} \right]^{\frac{-(1+\theta_p)}{\theta_p}} Y_{Dt}, \quad (1)$$

where  $\theta_p > 0$ , and  $P_{Dt}$  is an aggregate price index defined below. Similarly, in the foreign market, firm  $i$  faces the demand function:

$$X_t(i) = \left[ \frac{P_{Mt}^*(i)}{P_{Mt}^*} \right]^{\frac{-(1+\theta_p)}{\theta_p}} M_t^*, \quad (2)$$

where  $X_t(i)$  denotes the foreign quantity demanded of home good  $i$ ,  $P_{Mt}^*(i)$  denotes the price, denominated in foreign currency, that firm  $i$  sets in the foreign market,  $P_{Mt}^*$  is the foreign import price index, and  $M_t^*$  is aggregate foreign imports.

Each producer utilizes capital services  $K_t(i)$  and a labor index  $L_t(i)$  (defined below) to produce its respective output good. The production function has a constant-elasticity of substitution form:

$$Y_t(i) = \left( \omega_K^{\frac{\rho}{1+\rho}} K_t(i)^{\frac{1}{1+\rho}} + \omega_L^{\frac{\rho}{1+\rho}} (z_t L_t(i))^{\frac{1}{1+\rho}} \right)^{1+\rho}, \quad (3)$$

where  $z_t$  is a country-specific shock to the level of technology. Firms face perfectly competitive factor markets for hiring capital and labor.

The prices of intermediate goods are determined by Calvo-style staggered contracts, see Calvo (1983). Each period, a firm faces a constant probability,  $1 - \xi_p$ , to

reoptimize its price at home  $P_{Dt}(i)$  and probability of  $1 - \xi_{px}$  to reoptimize the price that it sets in the foreign country of  $P_{Mt}^*(i)$ . These probabilities are independent across firms, time, and countries. Following Galí and Gertler (1999) we allow for a mass  $\iota_p$  of backward-looking firms that sets its price based on a lagged information set. These firms set their price equal to the previous period Calvo reset price indexed by lagged inflation.

*Production of the Domestic Output Index.* A representative aggregator combines the differentiated intermediate products into a composite home-produced good  $Y_{Dt}$  according to

$$Y_{Dt} = \left[ \int_0^1 Y_{Dt}(i)^{\frac{1}{1+\theta_p}} di \right]^{1+\theta_p}. \quad (4)$$

The optimal bundle of goods minimizes the cost of producing  $Y_{Dt}$  taking the price of each intermediate good as given. A unit of the sectoral output index sells at the price  $P_{Dt}$ :

$$P_{Dt} = \left[ \int_0^1 P_{Dt}(i)^{\frac{-1}{\theta_p}} di \right]^{-\theta_p}. \quad (5)$$

Similarly, a representative aggregator in the foreign economy combines the differentiated home products  $X_t(i)$  into a single index for foreign imports:

$$M_t^* = \left[ \int_0^1 X_t(i)^{\frac{1}{1+\theta_p}} di \right]^{1+\theta_p}, \quad (6)$$

and sells  $M_t^*$  at price  $P_{Mt}^*$ :

$$P_{Mt}^* = \left[ \int_0^1 P_{Mt}^*(i)^{\frac{-1}{\theta_p}} di \right]^{-\theta_p}. \quad (7)$$

*Production of Consumption and Investment Goods.* Following Backus, Kehoe, and Kydland (1992) in assuming equal import content of consumption and investment, there is effectively one final good  $A_t$  that is used for consumption or investment, (i.e.,  $A_t \equiv C_t + I_t$ , allowing us to interpret  $A_t$  as private absorption).

Domestically-produced goods and imported goods are combined to produce final goods  $A_t$  according to

$$A_t = \left( \omega_A^{\frac{\rho_A}{1+\rho_A}} A_{Dt}^{\frac{1}{1+\rho_A}} + (1 - \omega_A)^{\frac{\rho_A}{1+\rho_A}} M_t^{\frac{1}{1+\rho_A}} \right)^{1+\rho_A}, \quad (8)$$

where  $A_{Dt}$  denotes the distributor's demand for the domestically-produced good and  $M_t$  denotes the distributor's demand for imports. The quasi-share parameter  $\omega_A$  determines the degree of home bias in private absorption, and  $\rho_A$  determines the elasticity of substitution between home and foreign goods. Each representative distributor chooses a plan for  $A_{Dt}$  and  $M_t$  to minimize its costs of producing the final good  $A_t$  and sells  $A_t$  to households at a price  $P_t$ . Accordingly, the prices of consumption and investment are equalized.

## 2.2 Households and Wage Setting

A continuum of monopolistically competitive households (indexed on the unit interval) supplies a differentiated labor service to the intermediate goods-producing sector. A representative labor aggregator combines the households' labor hours in the same proportions as firms would choose. This labor index  $L_t$  has the Dixit-Stiglitz form:

$$L_t = \left[ \int_0^1 N_t(h)^{\frac{1}{1+\theta_w}} dh \right]^{1+\theta_w}, \quad (9)$$

where  $\theta_w > 0$  and  $N_t(h)$  is hours worked by a typical member of household  $h$ . The aggregator minimizes the cost of producing a given amount of the aggregate labor index, taking each household's wage rate  $W_t(h)$  as given. One unit of the labor index sells at the unit cost  $W_t$ :

$$W_t = \left[ \int_0^1 W_t(h)^{\frac{-1}{\theta_w}} dh \right]^{-\theta_w}. \quad (10)$$

$W_t$  is referred to as the aggregate wage index. The aggregator's demand for the labor services of household  $h$  satisfies

$$N_t(h) = \left[ \frac{W_t(h)}{W_t} \right]^{-\frac{1+\theta_w}{\theta_w}} L_t. \quad (11)$$

The utility functional of a representative household  $h$  is:

$$\begin{aligned} & \tilde{\mathbb{E}}_t \sum_{j=0}^{\infty} \beta^j \left\{ \frac{1}{1-\sigma} \left( C_{t+j}(h) - \varkappa \frac{C_{t+j-1}}{\zeta} - \nu_{ct} \right)^{1-\sigma} \right. \\ & \left. + \frac{\chi_0}{1-\chi} (1 - N_{t+j}(h))^{1-\chi} + V \left( \frac{MB_{t+j+1}(h)}{P_{t+j}} \right) \right\}, \end{aligned} \quad (12)$$

where the discount factor  $\beta$  satisfies  $0 < \beta < 1$ . As in Smets and Wouters (2003), we allow for the possibility of external habits. At date  $t$  household  $h$  cares about consumption relative to lagged per capita consumption,  $C_{t-1}$ . The preference shock  $\nu_{ct}$  follows an exogenous first order process with a persistence parameter of  $\rho_\nu$ . The parameter  $\zeta$  controls for population size. The household's period utility function also depends on current leisure  $1 - N_t(h)$  and end-of-period real money balances,  $\frac{MB_{t+1}(h)}{P_t}$ . The liquidity-service function  $V(\cdot)$  is increasing in real money balances at a decreasing rate up to a satiation level. Beyond the satiation level, utility from liquidity services is constant. With this specification of the utility function, the demand for real money balances is always positive regardless of the level of the nominal interest rate.<sup>8</sup>

The budget constraint of each household is given by:

$$\begin{aligned} & P_t C_t(h) + P_t I_t(h) + MB_{t+1}(h) - MB_t(h) + \frac{1}{\phi_{bt}} [e_t P_{Bt}^* B_{Ft+1}(h)] - e_t B_{Ft}(h) \\ & = W_t(h) N_t(h) + \Gamma_t(h) - T_t(h) + R_{Kt} K_t(h) - P_{Dt} \phi_{It}(h). \end{aligned} \quad (13)$$

Final consumption and investment goods are purchased at a price  $P_t$ . Investment in physical capital augments the per capita capital stock  $K_{t+1}(h)$  according to a linear transition law of the form:

$$K_{t+1}(h) = (1 - \delta) K_t(h) + I_t(h), \quad (14)$$

where  $\delta$  is the depreciation rate of capital. The term  $R_{Kt} K_t(h)$  in the budget constraint represents the proceeds to the household from renting capital to firms.

---

<sup>8</sup>More formally, we follow Jeanne and Svensson (2007) in assuming that  $V(MB_{t+1}/P_t) < V_0$ ,  $V'(MB_{t+1}/P_t) > 0$ ,  $V''(MB_{t+1}/P_t) < 0$  for  $MB_{t+1} < \bar{m}$ , the satiation level of real money. And  $V(MB_{t+1}/P_t) = V_0$  for  $MB_{t+1} \geq \bar{m}$ , and  $V'(MB_{t+1}/P_t) \rightarrow \infty$  for  $MB_{t+1}/P_t \rightarrow 0$ .

Financial asset accumulation consists of increases in nominal money holdings  $MB_{t+1}(h) - MB_t(h)$  and the net acquisition of international bonds. Trade in international assets is restricted to a non-state contingent nominal bond.  $B_{Ft+1}(h)$  represents the quantity of the international bond purchased by household  $h$  at time  $t$  that pays one unit of foreign currency in the subsequent period.  $P_{Bt}^*$  is the foreign currency price of the bond, and  $e_t$  is the nominal exchange rate expressed in units of home currency per unit of foreign currency. Following Turnovsky (1985) households pay an intermediation fee  $\phi_{bt}$ .<sup>9</sup> The intermediation fee depends on the ratio of economy-wide holdings of net foreign assets to nominal output according to:

$$\phi_{bt} = \exp\left(-\phi_b \left(\frac{e_t B_{Ft+1}}{P_{Dt} Y_t}\right)\right). \quad (15)$$

If the home economy has an overall net lender position, a household will earn a lower return on any holdings of foreign bonds. By contrast, if the economy has a net debtor position, a household will pay a higher return on any foreign debt.

Households earn labor income,  $W_t(h) N_t(h)$ , lease capital to firms at the rental rate  $R_{Kt}$ , and receive an aliquot share  $\Gamma_t(h)$  of the profits of all firms. Furthermore, they pay a lump-sum tax  $T_t(h)$ . We follow Christiano, Eichenbaum, and Evans (2005) in assuming that households bear a cost of changing the level of gross investment from the previous period, so that the acceleration in the capital stock is penalized:

$$\phi_{It}(h) = \frac{1}{2} \phi_I \frac{(I_t(h) - I_{t-1}(h))^2}{I_{t-1}(h)}. \quad (16)$$

Households maximize the utility functional (12) with respect to consumption, investment, (end-of-period) capital stock, money balances, and holdings of foreign bonds, subject to the labor demand function (11), budget constraint (13), and transition equation for capital (14). They also set nominal wages in staggered contracts

---

<sup>9</sup>The assumption of an intermediation fee ensures that given our solution technique the evolution of net foreign assets is stationary. See Schmitt-Grohe and Uribe (2003) and Bodenstein (2011) for a discussion. The intermediation cost is asymmetric, as foreign households do not face these costs. Rather, they collect profits on the monopoly rents associated with these intermediation costs.

that are analogous to the price contracts described above. In particular, each member of a household is allowed to re-optimize its wage contract with probability  $1 - \xi_w$ . We allow for a mass  $\iota_w$  of backward-looking members within the household that sets its wage using a rule of thumb. These household members set their wages equal to the previous period reset wage indexed by lagged wage inflation.

### 2.3 Monetary and Fiscal Policy

Monetary policy follows an interest rate reaction function as suggested by Taylor (1993). However, when policy rates reach zero, we assume that no further actions are taken by the central bank. The notional rate that is dictated by the interest rate reaction function is denoted by  $i_t^{not}$ , whereas the actual policy rate that is implemented is denoted by  $i_t$ . The notional rate set as:

$$i_t^{not} = \bar{i} + \pi_t + \gamma_\pi(\pi_t - \bar{\pi}) + \frac{\gamma_y}{4} y_t^{gap}, \quad (17)$$

where  $\bar{i}$  and  $\bar{\pi}$  are the steady-state nominal interest rate and inflation rate, respectively. The actual (short-term) policy interest rate satisfies

$$i_t = \max(0, i_t^{not}), \quad (18)$$

and accordingly, the actual and notional rates differ only when the notional rate turns negative.

The term  $\bar{i}$  is the steady-state value for the nominal interest rate. The inflation rate  $\pi_t$  is expressed as the logarithmic percentage change of the domestic price level,  $\pi_t = \log(P_{Dt}/P_{Dt-1})$ . The term  $y_t^{gap}$  denotes the output gap, given by the log difference between actual and potential output, where the latter is the level of output that would prevail in the absence of nominal rigidities. Notice that the coefficient  $\gamma_y$  is divided by four as the rule is expressed in terms of quarterly inflation and interest rates.

Government purchases are a constant fraction of output  $\bar{g}$  and they fall exclusively on the domestically-produced good. These purchases make no direct contri-

bution to household utility. To finance its purchases, the government imposes a lump-sum tax on households that is adjusted so that the government’s budget is balanced every period.

## 2.4 Resource Constraints

The home economy’s aggregate resource constraint satisfies:

$$Y_{Dt} = C_{Dt} + I_{Dt} + G_t + \phi_{It}. \quad (19)$$

The composite domestically-produced good  $Y_{Dt}$ , net of investment adjustment costs  $\phi_{It}$ , is used to produce final consumption and investment goods ( $A_{Dt} = C_{Dt} + I_{Dt}$ ), or directly to satisfy government demand. Moreover, since each individual intermediate goods producer can sell its output either at home or abroad, there are also a continuum of resource constraints that apply at the firm level.

## 2.5 Calibration of Parameters and Solution Method

The model is calibrated at a quarterly frequency. The values of key parameters are presented in Table 1 and reflect fairly standard calibration choices for the U.S. economy. We choose  $\omega_A = 0.15$  to be consistent with an import share of output of 15%. The domestic and foreign population levels, respectively  $\zeta$  and  $\zeta^*$ , are set so that the home country constitutes 25% of world output. Balanced trade in steady state implies an import (or export) share of output of the foreign country of 5%. Because the foreign country is assumed to be identical to the home country except in its size,  $\omega_A^* = 0.05$ . We set  $\rho_A = 4$ , so that the price elasticity of import demand is 1.25.

We set the Calvo parameter for prices  $\xi_p$  to 0.9 and the parameter for wages  $\xi_w$  to 0.85 implying an average contract duration of 10 and about 6.5 quarters, respectively. We choose these parameters to curb the sensitivity of inflation in a way that compensates for the fact that the model abstracts from real rigidities in

price and wage setting. Export price rigidities have a shorter duration of 2 quarters, as implied by the parameter  $\xi_{px} = 0.5$ . We set  $\iota_p$ , the fraction of backward-looking price setters, to 0.75. Analogously, we set  $\iota_w$ , the fraction of backward-looking wage setters, to 0.75. Taken together, the choices of parameters regulating price and wage setting build a substantial degree of inertia in the price and wage inflation processes. This inertia prevents inflation from dropping precipitously in response to contractionary shocks in a way consistent with recent U.S. experience. Reducing the degree of inflation inertia would reinforce our results concerning the importance of the zero lower bound for the transmission of foreign shocks.

Monetary policy follows the modified Taylor rule (see Taylor 1999), aside from taking account of the zero lower bound constraint. Thus, the parameter  $\gamma_\pi$  on the inflation gap is 0.5 and the parameter  $\gamma_y$  on the output gap is 1. The steady state real interest rate is set to 1% per year ( $\beta = 0.9975$ ). Given steady state inflation equal to 2%, the implied steady state nominal interest rate is 3%. The values of remaining parameters are also fairly standard in the literature, and are summarized in Table 1.

Following Jung, Teranishi, and Watanabe (2005) and Eggertsson and Woodford (2003), all equilibrium conditions except the non-linear policy rule are linearized around the model's non-stochastic steady state. We solve the model using a piecewise linear algorithm described in Guerrieri and Iacoviello (2015). Because standard perturbation methods only provide a local approximation, they cannot capture the zero-lower bound constraint without adaptation. The method of Guerrieri and Iacoviello (2015) builds on an insight that has been used extensively in the literature on the effects of attaining the zero-lower bound on nominal interest rates.<sup>10</sup> That insight is that occasionally binding constraints can be handled as different regimes of the same model. Under one regime, the occasionally binding constraint is slack.

---

<sup>10</sup>Recent examples of the use of this technique include Jung, Teranishi, and Watanabe (2005), Eggertsson and Woodford (2003), Christiano, Eichenbaum, and Rebelo (2011b).

Under the other regime, the same constraint is binding. The piecewise linear solution method involves linking the first-order approximation of the model around the same point under each regime. Importantly, the solution that the algorithm produces is not just linear – with two different sets of coefficients depending on whether the occasionally binding constraint is binding or not – but rather, it can be highly nonlinear. The dynamics in one of the two regimes may crucially depend on how long one expects to be in that regime. In turn, how long one expects to be in that regime depends on the state vector. This interaction produces the high nonlinearity. Further details of the solution algorithm are given in the Technical Appendix.<sup>11</sup>

### 3 Initial Baseline Path

Our principal goal is to compare the impact of foreign shocks on the home country when it faces a liquidity trap with the effects that occur when policy rates can be freely adjusted. In the former case, the impact of a foreign shock depends on the economic conditions that precipitated the liquidity trap. Intuitively, the effects of an adverse foreign shock against the backdrop of a recession-induced liquidity trap in the home country should depend on the expected severity of the recession, and the perceived duration of the liquidity trap. In a shallow recession in which interest rates are only constrained for a short period, the effects of the foreign shock would not differ substantially from the usual case in which rates could be cut immediately.<sup>12</sup> By contrast, the effects of the foreign shock on the home country might be amplified substantially if it occurred against the backdrop of a steep recession in which policy rates were expected to be constrained from falling for a protracted period.

We use the term “initial baseline path” to describe the evolution of the economy that would prevail in the absence of the foreign shock. Given agents’ full knowledge

---

<sup>11</sup>The Technical Appendix is available from the CJE online archive at [economics.ca/cje/fr/archive.php](http://economics.ca/cje/fr/archive.php).

<sup>12</sup>In the case of a linear model, the effects of a shock are unrelated to the initial conditions.

of the model, the initial baseline path depends on the underlying shocks that push the economy into a liquidity trap, including their magnitude and persistence, as these features play an important role in determining agents' perceptions about the duration of the liquidity trap.

Our analysis focuses on the effects of foreign shocks against the backdrop of an initial baseline path that is intended to capture a severe recession in the home country. This “severe recession” baseline is depicted in Figure 2 by the solid lines. It is generated by a preference shock  $\nu_{ct}$  that follows an autoregressive process with persistence parameter equal to 0.7. The shock reduces the home country's marginal utility of consumption. As the shock occurs exclusively in the home country, the foreign economy has latitude to offset much of the contractionary impact of the shock by reducing its policy rate.

As shown in Figure 2 policy rates immediately fall to 0 and remain frozen at this level for ten quarters.<sup>13</sup> Given that the shock drives inflation persistently below its steady state value of 2% and that nominal interest rates are constrained from falling by the zero bound, real rates increase substantially in the near term. This increase in real interest rates accounts in part for the substantial output decline, which attains a trough of 8% below its steady state value. Real interest rates decline in the longer term, helping the economy recover. This longer term decline also causes the home currency to depreciate in real terms, and the ensuing expansion of real net exports mitigates the effects of the shock on domestic output. However, the improvement in real net exports is delayed due to the zero bound constraint, since higher real interest rates limit the size of the depreciation of the home currency in the near-term.

For purposes of comparison, Figure 2 also shows the effects of the same shocks when the home country's policy rates can be adjusted, i.e., ignoring the zero bound

---

<sup>13</sup>In Figure 2, most variables are plotted in deviation from their steady-state values, but the policy interest rate, the real interest rate, and inflation are shown in *levels* to highlight the zero bound constraint.

constraint. In this linear simulation, the home nominal interest rate falls more sharply and turns negative, implying a large and front-loaded decline in real interest rates. Hence, the fall in home output is smaller than in the benchmark framework in which the zero bound constraint is binding. The home output contraction is also mitigated by a more substantial improvement in real net exports. Given that real interest rates fall very quickly, the real depreciation is considerably larger, contributing to a faster improvement in real net exports.

## 4 International Transmission at the Zero Bound

We turn to assessing the impact of a negative foreign demand shock – specifically, a contractionary consumption taste shock  $\nu_{ct}^*$  – when the home country faces a liquidity trap. The foreign shock is scaled to induce a 1% reduction in *home* output in the case in which home monetary policy is assumed to be unconstrained by the ZLB. This scaling proves convenient for assessing the effects of the ZLB constraint on the transmission of the foreign shock to the home economy.

Figure 3 shows the “partial” effect of the foreign demand shock both for the case in which home monetary policy is unconstrained by the ZLB (the dashed red lines), and for the case in which it is constrained (the solid black lines). To be precise, the responses in Figure 3 are derived from a simulation that adds both the adverse domestic taste shock from Figure 2 and the foreign taste shock, and then subtracts the impulse response functions associated with the domestic taste shock alone.<sup>14</sup> Thus, all variables are measured as deviations from the baseline path shown in Figure 2.

As shown in Figure 3, the foreign preference shock leads to a contraction in foreign output of 3.5% (panel 2). Foreign policy rates are cut. As foreign real rates

---

<sup>14</sup>Because the model we solve is linear when the zero lower bound does not bind, the dashed lines in Figure 3 can alternatively be interpreted as the responses starting from the model’s steady state, rather than from the severe recession baseline.

also drop, foreign investment is stimulated. Lower foreign real rates contribute to a real exchange rate depreciation for the foreign economy. In turn, this depreciation boosts foreign exports. Perhaps surprisingly, the response of foreign GDP is nearly invariant to whether home monetary policy is constrained by the ZLB (as discussed below).

By contrast, the effects of the foreign demand shock on the home country are strikingly different depending on whether home monetary policy is constrained by the ZLB. While home GDP only falls about 1% when monetary policy is unconstrained – about 0.3 as large as the fall in foreign GDP – home GDP declines about twice as much when home monetary policy is constrained by the ZLB. Under either assumption about monetary policy, home real net exports contract because foreign absorption falls and the home real exchange rate appreciates (shown by the fall in panel 7, which reduces exports and boosts imports through standard relative price channels). However, in a liquidity trap, the decline in home export demand causes a fall in the home marginal cost of production and inflation that is not accompanied by lower policy rates. The zero bound constraint keeps nominal rates from declining for ten quarters. Real rates rise sharply in the short run, even though they fall at longer horizons. Consequently, domestic absorption does not expand as much as when policy rates can be cut immediately. If the initial recession were more pronounced, private absorption could even fall. With net exports falling and with domestic absorption not filling the gap, output falls by nearly as much in the home country as abroad.

The implication that the foreign GDP response is nearly invariant to the response of home monetary policy reflects that the home ZLB constraint has offsetting effects on foreign exports. In particular, while the home ZLB constraint reduces home absorption (relative to the unconstrained case) – which hurts foreign exports – it also induces a larger appreciation of the home currency – which benefits foreign exports. With a reasonable calibration of trade price elasticity of around unity, it turns out

that these effects on foreign exports (and hence GDP) nearly counterbalance each other.

The magnification of the spillover effects of foreign shocks to the home economy when the ZLB binds is not particular to the consumption shock but also applies, for instance, to shocks to the discount factor, capital tax rates, and government spending.<sup>15</sup> The case of technology shocks is discussed later in this section.

#### 4.1 An Alternative “Secular Stagnation” Baseline

We will next show how the effects of foreign demand shocks vary with the duration of the liquidity trap in the home economy. The liquidity trap in the home economy could be longer either because domestic conditions are comparatively worse, or because the foreign demand shock was sufficiently large and adverse, or both. Either way, an incremental contraction in foreign demand will have a bigger contractionary effect on home GDP when the ZLB binds for a longer duration.

But with this prelude, it is interesting to focus on how foreign demand shocks may potentially push an economy with a low “neutral” policy rate into recession, and exert nonlinear effects on home GDP as the shock increases in size. To do so, we modify our baseline calibration to set the inflation target equal to 0.2%, and the discount factor to 0.99925, consistent with a steady state real interest rate of 0.3%. The implied steady state nominal interest rate of 0.5% is similar to that in Japan prior to the Global Financial Crisis. As we discuss below, although this calibration is admittedly quite pessimistic about the long-run neutral rate, it is useful both for showing how the effects of foreign shocks grow with the length of the liquidity trap (the more general point), and for highlighting some of the risks of a very low neutral rate.

In this vein, Figure 4 shows the effects of three foreign demand shocks of varying

---

<sup>15</sup>The effects of shocks to the discount factor, capital tax rates, and government spending are shown in the working paper version of this article, see Bodenstein, Erceg, and Guerrieri (2009).

size. Importantly, the figure shows responses relative to the steady state baseline – unlike Figure 3, the foreign shocks are the only source of disturbance. The first shock (solid line) is scaled to reduce foreign GDP by 3%. This shock is too small to drive the home economy to the ZLB, and hence reduces home GDP by 0.85% (consistent with the partial effect of the foreign demand shock in Figure 3).

The second shock (dashed line) is double in size relative to the first one. As foreign policy rates can be cut aggressively, the effect on foreign GDP is almost linear, with foreign GDP declining just shy of 6%. By contrast, home policy rates cannot be cut as much as the policy rule would dictate and the ZLB binds for almost 10 quarters. Accordingly, home GDP declines more sharply and nonlinearly. It drops about 2.2%, or 30% more than the 1.7% drop that a mere doubling of the effects of the first shock would dictate. To put it differently, the “marginal” effect on home GDP of the additional 3% decline in foreign GDP is about 1.35% ( $2.2 - 0.85 = 1.35$ ), which is much larger than the 0.85% home GDP decline implied by the first shock.

The nonlinear effects associated with the zero lower bound in the home country are even more pronounced for the third shock (the dash-dotted line). This third shock is double the size of the second shock (or four times the size of the first one). Again, as the foreign country can adjust the policy rate, foreign GDP declines close to 12%, almost double the GDP decline for the second shock. By contrast, as the shock now takes the home policy rate to the lower bound for almost 15 quarters, the magnification of the effects of the shock on the home country is much more than double, and home GDP declines over 6%, about three times the size of the GDP decline for the second shock. One simple way of summarizing the nonlinear effects associated with different durations of the liquidity trap in the home country is by the ratio of the GDP decline at home and abroad. When the foreign shocks are small enough to keep the economy away from the zero lower bound, the ratio of home and foreign GDP is 0.35 on impact and declines thereafter. The line shown in the inset

box for the first 5 quarters under a linear approximation to the model's solution would be invariant to the size of the shock. By contrast, as the home economy hits that ZLB for the second shock, this ratio increases to 0.42. Finally, as the expected duration of the ZLB is even longer for the third shock, the ratio of home to foreign GDP jumps to 0.62.

The implication of Figure 4 that foreign shocks alone may drive the home economy into recession – even in the absence of financial spillovers from which the model abstracts – may appear to hinge on somewhat extreme assumptions about the neutral policy rate and size of the foreign shocks. Even so, it is useful to underscore that the larger foreign GDP declines of 6-12% considered in the second and third scenarios seem reasonably consistent with the experience of many industrial economies during the GFC and its aftermath. For example, an IMF study estimated that GDP in OECD economies fell by 14% on average relative to its pre-crisis trend over the 2008-2012 period (Abbas et al. 2014). More generally, it is not essential that the steady-state nominal interest rate be as low as the 0.5% assumed in Figure 4 – nor for foreign shocks to be as large – in order for the spillovers from foreign shocks to be similar to those shown in Figure 4. For example, the spillovers would be large if the home economy had a considerably lower steady-state nominal interest rate than in our baseline (say 1.5 or 2%, rather than 3%), but was also experiencing a modest recession due to domestic shocks. The more general upshot of our analysis is that a low neutral rate tends to significantly heighten the vulnerability of the domestic economy to foreign shocks.

To illustrate how a drift towards secular stagnation could interact with a trend towards globalization, the next two sections study how the nonlinear transmission of foreign shocks associated with reaching the ZLB is influenced by the home economy's trade share and by the substitutability of the home and foreign traded goods. For this purpose, we continue to use the same calibration as above, which implies a steady-state nominal interest rate of 0.5%.

## 4.2 Changes in Openness

Figure 5 considers the same large foreign consumption shock leading to a decline in foreign GDP of close to 12%, as was considered for the third shock in Figure 4. The dashed-dotted lines denote the effects associated with the benchmark 15% import share. The figure also shows the effects of the same foreign shock for a lower trade share of 10% and for a higher trade share of 20%. The results shown in the left-hand-side panels (panels 1, 3, 5, and 7) pertain to a configuration of the model for which the ZLB in the home country is not enforced, while the results shown in the right-hand-side panels (panels 2, 4, 6, and 8) pertain to a configuration of the model for which the ZLB is enforced.

When the ZLB is not enforced, the effects of the foreign shock on home GDP increase in a nearly linear fashion with the trade share as the trade share increases from 10 to 20 percent (Panel 1). This near-linearity reflects both that the contractionary effect on GDP arising through net exports increases nearly in line with the trade share (as suggested by the response of the export share in Panel 5), and also that the boost to GDP from higher absorption rises nearly proportionately (Panel 3). A deeper cut in policy rates (Panel 7) is clearly required in a more open economy in order to achieve the larger rise in absorption.<sup>16</sup>

By contrast, when the ZLB is enforced, the effects of the same foreign demand shock on home GDP are not only much larger, but show much greater variation with the trade share. This larger variation in home GDP simply reflects that bigger cuts in the policy rate are required to crowd in domestic demand when trade openness is higher, but such cuts are infeasible due to the ZLB. As a result, domestic absorption in an economy with a trade share of 20 percent rises only a bit more than in the economy with a trade share of 10 percent (panel 4), even though the hit to real net

---

<sup>16</sup>For larger increases in the trade share than considered in Figure 5, real GDP turns out to rise somewhat less than linearly with the trade share, mainly because monetary policy is effective in crowding in domestic demand.

exports is much larger in the former. The upshot is that the more open economy experiences a liquidity trap lasting almost twice as long (panel 8), and a GDP contraction triple in size, as the economy with the 10 percent trade share.

### 4.3 Changes in Substitutability of Home and Foreign Goods

The value of the import price elasticity of demand is an important determinant of the duration of a liquidity trap and the spillover effects of country-specific shocks. When the zero bound is not binding, increasing the trade price elasticity of demand magnifies the decline of home real net exports caused by a foreign demand contraction. The spillover effects on home output are partly offset by a more vigorous reaction of domestic monetary policy. However, in a liquidity trap, monetary policy is unable to compensate in such a manner, and the larger effects on real net exports translate into greater effects on home output.

Figure 6 shows how the spillover effects of a foreign consumption shock are affected by a higher elasticity, equal to 2 versus 1.25 in our original calibration, or a lower elasticity, equal to 0.75. The figure considers, again, the spillover effects on the home economy of a foreign consumption shock that brings about a 12% reduction in foreign GDP. As in Figure 4, panels on the left-hand-side are from a configuration that disregards the ZLB. Panels on the right-hand-side are from a configuration of the model with the ZLB enforced.

Away from the zero lower bound, the higher import-price elasticity reduces the responsiveness of exchange rates to country-specific shocks. However, the increased sensitivity to movements in relative import prices more than offsets the decreased volatility of exchange rates. Accordingly, with the higher elasticity, home country net exports drop by more in response to a contractionary foreign consumption shock, leading to a larger fall in home GDP. The larger drop in activity leads to a larger drop in policy rates and a longer duration of the ZLB, which then further reinforces the output decline associated with a larger trade elasticity.

In sum, as trade volumes continue to expand and domestic and foreign goods continue to become closer substitutes in line with globalization trends, we can expect that the spillover effects of foreign contractionary shocks may be augmented even more when domestic monetary policy is constrained by the ZLB.

#### 4.4 A Foreign Technology Shock

Near unit-root technology shocks are the typical source of fluctuations in open economy models. However, the spillover effects of country-specific technology shocks are quite small and remain so even in a liquidity trap. The basic reason is that lower foreign activity reduces the demand for home exports, but this effect is counterbalanced by a depreciation of the home real exchange rate, which boosts home exports. Returning to our benchmark calibration with nominal interest rates at 3%, the exchange rate channel initially dominates, as shown in Figure 7, implying a rise in home real net exports, and a small and short-lived *expansion* in home GDP. The effects when the home country is constrained by the zero lower bound are only modestly different.

### 5 Conclusions

When monetary policy is unconstrained, it can cushion the impact of foreign disturbances. By contrast, in a liquidity trap, monetary policy cannot crowd in domestic demand as effectively, and the spillover effects of foreign shocks can be magnified greatly. The amplification of idiosyncratic foreign shocks depends on both the duration of the liquidity trap and on key structural features such as the trade price elasticity. The size of the foreign shock is of particular importance as it can affect the length of the liquidity trap and thereby decouple the marginal and average spillover effects of the shock. With our autoregressive shock processes, as typically postulated in the empirical validation of DSGE models, the model can generate

substantial differences between the marginal and the average effect of a shock. A simplification of the treatment of the zero lower bound that fixed the duration of the liquidity trap exogenously would miss this feature completely.

Developments during the Global Financial Crisis and its aftermath suggest that foreign shocks may have much larger effects on the domestic economy when monetary policy is constrained from adjusting interest rates. Should neutral policy rates drift downwards, foreign contractionary shocks could have outside effects even for relatively closed economies such as the United States, much as they did for Japan during the Global Financial Crisis.
